Introduction

The production of ornamental plants, including both nursery and floriculture crops, is a thriving and quickly expanding industry. Over a six-year span, the value of this industry in the United States increased over 23% to $14.3 billion in 2002 (12,33). Ornamental plant production is also a major industry in Australia, Canada, Europe, and South America. The U.S. Department of Agriculture (USDA) recognizes deciduous and evergreen trees, woody ornamental plants, and shrubs as nursery crops, while floriculture crops include foliage plants, cut flowers, flowering potted plants, and bedding plants (30,31). The wholesale value of the entire floriculture crop in 2002 was estimated to be worth $4.8 billion. California and Florida lead the nation in floriculture crop production ($1.8 billion in 2002), and combined these two states produce almost 40% of total U.S. wholesale floriculture sales (32).

Many floriculture crops are produced in the U.S. including geranium (Pelargonium x hortorum), chrysanthemum (Dendranthema morifolium), gladiolus (Gladiolus spp.), and daylily (Hemerocallis spp.). The value of the U.S. wholesale potted geranium crop from cuttings and seeds was $150 million in 2002 (32). Geraniums also have a substantial market as flowering hanging baskets and potted flowering plants. The U.S. wholesale crop of chrysanthemum was valued at $103 million for potted flowering bedding plants and $77 million for potted flowering foliage plants in 2001 (32). Gladiolus production for cut flowers in the U.S. in 2001 totaled $24.2 million (32). Daylilies are popular landscape plants that along with other herbaceous perennials were valued at $571 million in 2002 (32).
One serious disease that can negatively affect production of many ornamental crops is a fungal infection called rust. Infected plants develop lesions (pustules) on the lower surfaces of plant leaves which increase in size and eventually rupture the epidermis and release spores. These spores are typically brightly colored and are characteristic in diagnosing rust infections (Fig. 1). Pustules also can be present on the upper surface of leaves and can coalesce to form large necrotic areas (Fig. 2). Severe infections can result in premature leaf drop. Rust pustules also can form on stems and scapes, if present (Fig. 3). Rust spores are carried easily on wind currents and also can be disseminated by water splash, but long-distance dispersal of rusts on ornamental plants is mainly attributed to the movement of infected plants. Rust fungi typically have complex lifecycles involving one (autoecious) or two (heteroecious) hosts. Over 125 species of fungi that cause rust have been reported on 56 different ornamental crops (4). Examples of some of these rusts are presented in Table 1.

Integrated management practices, including scouting, proper sanitation, use of resistant varieties (if available), and preventative fungicide applications, are used to manage rust outbreaks in floriculture crops and minimize potential disease losses (4,13). Several chemical classes of fungicides are registered for and have efficacy against rusts on ornamental crops. These include the strobilurins (e.g., azoxystrobin), sterol biosynthesis inhibitors (e.g., myclobutanil, propiconazole), and broad-spectrum protectants (e.g., chlorothalonil, mancozeb) (10).

Rusts have the potential to dramatically affect floriculture production because these pathogens cannot be adequately detected on symptomless but contaminated or infested propagation material entering the U.S. or moving state-to-state. For example, quiescent rust spores can easily lodge in the crown of plants that have had foliage removed for shipping purposes (Fig. 4). Symptomless plants then can be moved long distances through international or interstate trade, dispersing the pathogen and introducing it into areas that were previously pathogen-free (28). Rust fungi are obligate parasites that do not usually kill infected plants. However, infection by rusts will reduce plant health and vigor, reduce flower production, and decrease the aesthetic value of ornamental crops due to the presence of pustules. Also, quarantine restrictions and eradication efforts can be costly and have a significant economic impact on floriculture production.

**Plant Quarantines**

Plant quarantines can be used to restrict the movement of plants into the U.S. and to limit state-to-state movement of plants. Regulatory control of ornamental plants was recently reviewed by Stebbins and Johnson (28). The first federal regulatory act designed to control the introduction of foreign pests into the U.S. was passed into law in 1912. This law, called the Plant Quarantine Act, and ensuing regulations help prevent or delay the introduction of foreign pathogens, including rusts, into the U.S. Rust pathogens of ornamental crops that are currently on the Plant Protection and Quarantine (PPQ) Regulated Pest List are found in Table 2. Quarantines have been used to limit movement of rust pathogens of geranium, chrysanthemum, daylily and gladiolus into the United States. A complete list of plant pathogens regulated by the U.S. Animal and Plant Health Inspection Service (APHIS) can be found at the USDA APHIS web page.

*b* Listed as Chrysomyxa leaf rust on the American Phytopathological Society list of common names of plant diseases.

**Examples of Quarantines Proven Effective in the U.S.**

1. **Chrysanthemum white rust.** Chrysanthemum white rust, caused by the fungus *Puccinia hoviana*, is presently classified as a quarantine significant pathogen in the U.S. (Table 2) and Australia. This rust has been described as the most serious disease of greenhouse-produced chrysanthemums because infected plants are unmarketable resulting in large economic losses (15,21,22,25). *Puccinia hoviana* is an autoecious rust pathogen that is native to Asia. Infections are characterized by yellow lesions on the upper leaf surface that become necrotic. White pustules, which produce teliospores and basidiospores under favorable environmental conditions, develop on the lower leaf surface (1).

Chrysanthemum white rust was introduced into England from Japan in 1963 (36). For more than twenty years an eradication campaign and quarantine measures were in place to prevent movement of the pathogen. These measures were ultimately unsuccessful and in 1989 the quarantine was lifted. Chrysanthemum white rust is now endemic in England (36). The rust has also become endemic in the Netherlands, which exports almost half of their chrysanthemum cuttings and flowers (25). Colombia, which is the second largest flower exporter behind the Netherlands, sends 97% of its total chrysanthemum exports to the U.S. (22). White rust has been present in Colombia since the late 1980s and eradication efforts have been in place to remove the pathogen from export producing areas. If white rust were to be detected on imported plant material.
from Colombia, all U.S. imports would be stopped, resulting in enormous financial losses for Columbian producers and U.S. distributors. A strict eradication and control campaign has been implemented in Colombia to keep all chrysanthemum exports free of P. horiana (22). This campaign has been funded by emergency funds obtained from Colombian growers and financial backing from the flower industry (22).

Isolated outbreaks of white rust have occurred in the 1990s in New Jersey, Pennsylvania, Washington, and Oregon (1,3). The discovery of white rust on chrysanthemum plants in production areas of California in 1992 prompted a reevaluation of the eradication program in place for control of the disease (3). Weekly sprays of triazole or strobilurin fungicides such as azoxystrobin, hexaconazole, myclobutanil, and propiconazole were found to be suitable regulatory treatments for exclusion and eradication of this pathogen (3,15,19). However, in 2001 isolates of white rust insensitive to both the triazole and strobilurin classes of chemicals were found in England (5). Outbreaks of white rust in the U.S. have been limited, and the quarantine is still deemed effective (1,3).

2. Gladiolus rust. Six gladiolus rust pathogens (Puccinia gladioli, P. mccleanii, Uredo gladioli-buettneri, Uromyces gladioli, Uromyces nyikensis, Uromyces transversalis) are listed as quarantine significant pathogens by the PPQ (Table 2). Transverse leaf rust (Uromyces transversalis) is an autoecious rust pathogen native to South Africa. The fungus spread into production areas of Europe and South America in the late 1960s (17) and into Australia in the 1990s (2). The rust is characterized by orange pustules that form on the leaf surface. Pustules can also form on the inflorescence and flower spike of the plant. The disease has resulted in 100% losses and has made production of gladiolus for cut flowers almost impossible without fungicide use in parts of Africa (6).

Examples of Quarantines Proven Ineffective in the U.S.

1. Daylily rust. Daylily rust caused by Puccinia hemerocallidis is a heteroecious rust native to Southeast Asia. The alternate host is the herbaceous perennial Patrinia (20). Yellow pustules form on leaf surfaces (Fig. 1). These pustules produce urediniospores that can continually re-infect the host and spread to other daylilies. The pathogen was first detected in Florida and Georgia production areas in 2000 (38) and later identified as P. hemerocallidis (9). Although it is suspected that the infected plants came from Central America, the original source of the inoculum has not been pinpointed (37,38). By fall of 2001, the rust was present in over 24 states within the U.S. and Costa Rica (9,35). The pathogen was officially quarantined, and plant movement was regulated in the U.S. in 2001 (35). In 2002, daylily rust was recognized as endemic in the southeastern U.S. Containment of the pathogen in the U.S. was deemed unrealistic due to widespread movement of plants by hobbyists and nurseries and the USDA PPQ lifted the federal quarantine in January 2002.

2. Geranium rust. Geranium rust caused by Puccinia pelargonii-zonalis infects the zonal geraniums (Pelargonium x hortorum) (26). Puccinia pelargonii-zonalis is an autoecious rust pathogen that produces dark brown urediniospores on the lower surfaces of the leaves and chlorotic halos on the upper leaf surface (8). As lesions age, concentric rings of urediniospores are produced (Fig. 5). The pathogen was introduced into Europe from South Africa in the early 1960s and by 1967 it had been introduced into greenhouses in California, New York, and Canada (18). Despite quarantine restrictions and the destruction of infected plants, the rust became
endemic in Europe and California by the 1970s (27). The constant re-
introductions of the pathogen into production areas led to the lifting
of most quarantines in the early 1980s (29). In 1997, an epidemic of
this rust negatively impacted commercial geranium production in the
southeastern U.S. (11).

Why Do Quarantines Fail?
Many factors can contribute to the introduction of rust-infected
stock into commercial production areas. International trade of
ornamental crops has made the exclusion of rust pathogens difficult
because contaminated plant parts may be symptomless and
inadvertently allowed to enter quarantined areas. With repeated
introductions pathogens may become endemic causing the quarantine
to fail. The inability to adequately detect rust pathogens on
contaminated or infected propagation materials severely hinders
quarantine efforts. While rusts can be easily diagnosed when
sporulating lesions are present, young non-sporulating lesions are
often small and may remain undetected if only a few pustules are
present in a shipment of tens of thousands of plants. Improved
detection methods are needed to more accurately diagnose infections.
New diagnostic methods and keys are being developed to more
quickly and accurately identify quarantined pathogens (34). The
effective implementation of these techniques must be the next step in
quarantine enforcement.

Quarantines may also fail when rust-infected crops are
unregulated. For example, daylily hobbyists and hybridizers can trade
and sell plants in federally unregulated markets, such as farmers’
markets and trade shows. This compromises the effectiveness of
quarantines and was one of the reasons for lifting the daylily rust
quarantine in 2002 (35). Some of the isolated outbreaks of
chrysanthemum white rust in North America also were attributed to
hobbyists bypassing inspectors when transporting cuttings (1). To
ensure the effectiveness of quarantines, the information exchange
between federal agencies and hobbyists should be improved to better
inform growers of the potential implications of moving infected plants.

New fungicidal developments in the 1980s and 1990s, led to
fungicides such as myclobutanil and azoxystrobin that have eradicant
or curative activity for some rust fungi (3,5). This technology can
ease the pressure on quarantine restrictions, because the fungus can
theoretically be eradicated from diseased shipments, allowing trade to
continue. The chrysanthemum white rust quarantine and eradication
campaign in England was ended in 1989, after propiconazole was
proven to be effective at eradicating the pathogen (36). However, the
reliance on chemical controls as the sole means of managing white
rust contributed to the development of fungicide resistance in *P. horiana* (5). Additional research is needed to determine if different fungicides display curative activity against a variety of rust pathogens, and to develop treatments that kill quiescent spores on plant foliage. Adopting sound disease management practices, whether rusts are endemic or not, will help prevent future outbreaks and minimize existing problems.
